Abstract

We calculate density–density correlations of an expanding gas of strongly attractive ultra-cold spin-1/2 fermions in an optical lattice. The phase diagram of the tightly bound fermion pairs exhibits a Bose–Einstein condensed state and a Mott insulating state with a single molecule per lattice site. We study the effects of quantum fluctuations on the correlations in both phases and show that they are especially important in the Bose–Einstein condensate state, leading to the appearance of singular peaks. In the Mott insulating state, the correlations are characterized by sharp dips. This can be utilized in experiments to distinguish between these two phases.

1. Introduction

Experiments with ultra-cold atoms have opened many directions to study ground-state properties of complex many-body systems, such as Bose–Einstein condensation and fermion pairing. The introduction of optical lattices has added the possibility of creating new ground states [1]. A prominent example is the formation of a Mott insulating (MI) phase for strongly interacting bosons [2] or fermions [3].

Another interesting direction was brought to the field by the unprecedented control over the interaction between atoms via a magnetic Feshbach resonance [4]. By means of the latter it became possible to turn fermions with two hyperfine internal states into bosons [5] by pairing. For weak attraction, the Bardeen–Cooper–Schrieffer (BCS) theory predicts an instability towards formation of large Cooper pairs, whose size can be much larger than the separation between atoms in the Fermi gas. If the attraction is made stronger, then these Cooper pairs become smaller and eventually, for very strong interaction, they behave as point-like (hard-core) bosonic molecules. Although there is no sharp distinction between the BCS state and a condensate of local pairs of fermions, the cross-over from the weakly interacting to the strongly interacting Fermi gas is of substantial interest [6]. In the presence of an optical lattice, the tightly bound molecules in the BEC (Bose–Einstein condensate) regime may undergo a quantum phase transition from a BEC state to a MI state with one particle per lattice site. This leaves us

with the question of how to identify the two phases by simple measurements.

A clear signature of superfluidity in a system of bosons is the presence of sharp density peaks due to phase coherence in time-of-flight experiments [2]. In the MI phase, on the other hand, the density peaks are washed out due to the absence of phase coherence (see [7]). To characterize this phase, it is useful to study the noise correlations in the Fermi gas [8]. Noise correlations have been investigated for weakly interacting Fermi gases in an optical lattice. As a characteristic feature, a correlation hole was observed experimentally [9].

In this paper, we study density–density correlations of an expanding gas of ultra-cold spin-1/2 fermions realized in an optical lattice. We discuss that the density–density correlations reveal the fermionic nature of the gas in the MI state and its bosonic nature in the Bose–Einstein condensate (BEC). We show that the effects of quantum fluctuations on the correlations are important.

2. Model

An effective Hamiltonian for fermions in an optical lattice near a Feshbach resonance was derived in [10]. Under typical experimental conditions, the resulting Hamiltonian can be mapped to an effective single-band model, which comprises the local dressed bosonic molecules and individual fermionic atoms separately. In this paper we consider a purely fermion

model in an optical lattice with attractive interaction and with two internal states, denoted by the pseudospin projections $\uparrow$ and $\downarrow$, respectively. The number of fermions in the two components is equal. The fermionic field operator $\hat{\psi}_\sigma(\mathbf{r})$ is expanded in a basis of Wannier functions [11] as

$$\hat{\psi}_\sigma(\mathbf{r}) = \sum_{i,n} w_n(\mathbf{r} - \mathbf{R}_i)\hat{c}_{i,n,\sigma}, \tag{1}$$

which allows us to use the tight-binding representation. Here, $\hat{c}_{i,n,\sigma}$ is the annihilation operator for particles in the Wannier state n at lattice site $\mathbf{R}_i$. For a deep optical lattice, only the lowest Wannier state is taken into account with $\hat{c}_{i,\sigma} \equiv \hat{c}_{i,0,\sigma}$. In this case, the lattice Hamiltonian in d dimensions reads

$$\hat{H} = -\frac{\bar{t}}{2d} \sum_{\sigma=\uparrow,\downarrow} \sum_{\langle i,j \rangle} \hat{c}_{i\sigma}^\dagger \hat{c}_{j\sigma} - \frac{J}{2d} \sum_{\langle i,j \rangle} \hat{c}_{i\uparrow}^\dagger \hat{c}_{j\uparrow} \hat{c}_{i\downarrow}^\dagger \hat{c}_{j\downarrow}$$
$$- \sum_{\sigma=\uparrow,\downarrow} \sum_i \mu_\sigma \hat{c}_{i\sigma}^\dagger \hat{c}_{i\sigma}. \tag{2}$$

Nearest-neighbor tunneling of the individual fermions is described by the parameter $\bar{t}$. Moreover, there is also a nearest-neighbor attraction with parameter J which can be understood as a tunneling term of fermionic pairs (molecular tunneling). A similar model of a mixture of hard-core bosons and fermions in a lattice was discussed in [12]. However, in our model the hard-core bosons $\hat{b}_i$ are given by pairs of fermion operators $\hat{c}_{i\uparrow}\hat{c}_{i\downarrow}$. This means that the fermions can transmute dynamically into hard-core bosons by local pairing.

3. Phase diagram

We apply the functional integral formalism developed for the Hamiltonian in equation (2) in [13, 14]. The partition function of a grand-canonical ensemble of fermions with chemical potential μ at inverse temperature β can be expressed in terms of an integral over a fermionic (Grassmann) field ψ and complex molecular fields ϕ, χ as

$$Z = \int e^{-\int_0^\beta d\tau \mathcal{L}} \mathcal{D}[\psi, \phi, \chi] \tag{3}$$

with the Lagrangian

$$\mathcal{L} = \sum_{i,j} \bar{\phi}_i \hat{v}_{i,j}^{-1} \phi_j + \frac{1}{2J} \sum_i \bar{\chi}_i \chi_i - \sum_{i,j} \hat{\mathcal{C}}_i^\dagger \hat{\mathbf{G}}_{ij}^{-1} \hat{\mathcal{C}}_j, \tag{4}$$

where we have used the notation $\hat{\mathcal{C}}^\dagger = (\psi_\uparrow, \bar{\psi}_\downarrow)$ and $\hat{\mathcal{C}} = (\psi_\downarrow, \bar{\psi}_\uparrow)^T$, and with the inverse fermionic Green's matrix

$$\hat{\mathbf{G}}^{-1} = \begin{pmatrix} -i\phi - \chi & \partial_\tau + \mu + \bar{t} \\ \partial_\tau - \mu - \bar{t} & i\bar{\phi} + \bar{\chi} \end{pmatrix}. \tag{5}$$

Here $\hat{v}_{i,j} = \frac{J}{2d}\delta_{|i-j|,1}$. $\hat{t}$ is the nearest-neighbor tunneling matrix with elements $\bar{t}/2d$.

The integration over the complex molecular fields ϕ, χ can be performed in saddle-point approximation [13, 14]. For a vanishing fermionic tunneling, i.e. by assuming a situation where all fermions are paired up, the phase diagram is depicted in figure 1. There are three phases: the BEC of molecules with the condensed fraction $n_0 = (J^2 - 4\mu^2)/(4J^2)$, the MI state with one particle per site and $n_0 = 0$, and the empty phase. Fluctuations around the saddle point provide the low-energy
Figure 1. Phase diagram for $\bar{t} = 0$ and $k_B T = 0$. The three phases are the BEC with a non-vanishing condensed density, the MI states with vanishing condensed density and with one molecule per lattice site, and the empty phase. μ and J are in arbitrary energy units.

excitations of the bosonic molecules. They are gapless in the BEC phase:

$$\epsilon_\mathbf{k} = \sqrt{4J^2 g_\mathbf{k} n_0 + 4g_\mathbf{k}^2 \mu^2}, \tag{6}$$

where $g_\mathbf{k} = 1 - 1/d \sum_{i=1}^d \cos k_i$ is the dispersion of the free Bose gas. On the other hand, the excitations of the MI state have a gap $\Delta = 2\mu - J > 0$:

$$\epsilon_\mathbf{k} = \Delta + J g_\mathbf{k}. \tag{7}$$

4. Density–density correlations

In a typical experiment with ultra-cold atoms, it is not easy to identify the spin projection. Therefore, the detected fermion density should be described by a superposition of both spin projections. For this purpose, we introduce the spin-independent fermionic density $\hat{n} = \hat{n}_\uparrow + \hat{n}_\downarrow$. Then the truncated density–density correlation function in a time-of-flight experiment is given under the assumption that the atoms expand freely after they have been released from the optical lattice as [15]

$$C_{\mathbf{r},\mathbf{r}'} \equiv \langle \hat{n}(\mathbf{r})\hat{n}(\mathbf{r}') \rangle - \langle \hat{n}(\mathbf{r}) \rangle \langle \hat{n}(\mathbf{r}') \rangle$$
$$= \left(\frac{M}{\hbar t}\right)^{2d} \langle \hat{n}(\mathbf{k})\hat{n}(\mathbf{k}') \rangle - \langle \hat{n}(\mathbf{r}) \rangle \langle \hat{n}(\mathbf{r}') \rangle. \tag{8}$$

Here $\mathbf{k}$ is related to $\mathbf{r}$ by $\mathbf{k} = M\mathbf{r}/\hbar t$ with the mass of atoms $M \propto \hbar/J$. Free expansion assumes that atoms evolve independently. This can be achieved by switching off an optical lattice as well as by switching the magnetic field to values far from the strongly attractive regime suddenly before the expansion [8, 16]. The above formula then reveals that the density distribution, observed after a fixed time-of-flight, is related to the momentum distribution of the particles trapped in the lattice before the expansion. It is widely used to analyse ground state properties of ultra-cold atoms trapped by an optical lattice [17].

Now we use the expansion of equation (1) to express the density–density correlation of equation (8) in terms of the coordinates of the underlying optical lattice as

$$C_{\mathbf{r},\mathbf{r}'} = \left(\frac{M}{\hbar t}\right)^{2d} |\tilde{w}(\mathbf{k})|^2 |\tilde{w}(\mathbf{k}')|^2 \sum_{i,i',j,j'}$$
$$\times \sum_{\alpha,\beta=\uparrow,\downarrow} e^{i\mathbf{k}(\mathbf{R}_i-\mathbf{R}_{i'})+i\mathbf{k}'(\mathbf{R}_j-\mathbf{R}_{j'})} \langle \hat{c}_{i\alpha}^\dagger \hat{c}_{j\beta}^\dagger \hat{c}_{j'\beta} \hat{c}_{i'\alpha} \rangle,$$
$$+ \langle \hat{n}(\mathbf{r})\rangle \delta(\mathbf{r}-\mathbf{r}') - \langle \hat{n}(\mathbf{r})\rangle\langle \hat{n}(\mathbf{r}')\rangle, \qquad (9)$$

where $\tilde{w}$ is a Fourier transform of the Wannier function. Using the saddle-point approximation of the complex fields (ϕ, χ), we can evaluate $\langle \hat{c}_{i\alpha}^\dagger \hat{c}_{j\beta}^\dagger \hat{c}_{j'\beta} \hat{c}_{i'\alpha}\rangle$. Since the fermion field appears only in a quadratic form in equation (4), the integration is given by a Wick contraction of pairs of fermions:

$$\langle \hat{c}_{i\alpha}^\dagger \hat{c}_{j\beta}^\dagger \hat{c}_{j'\beta} \hat{c}_{i'\alpha}\rangle = \langle \hat{c}_{i\alpha}^\dagger \hat{c}_{i'\alpha}\rangle\langle \hat{c}_{j\beta}^\dagger \hat{c}_{j'\beta}\rangle - \langle \hat{c}_{i\alpha}^\dagger \hat{c}_{j'\beta}\rangle\langle \hat{c}_{j\beta}^\dagger \hat{c}_{i'\alpha}\rangle$$
$$+ \langle \hat{c}_{i\alpha}^\dagger \hat{c}_{j\beta}^\dagger\rangle\langle \hat{c}_{j'\beta} \hat{c}_{i'\alpha}\rangle. \qquad (10)$$

The fermionic expectation values on the right-hand side are matrix elements of the fermionic Green's function $\hat{\mathbf{G}}$ of equation (5):

$$\langle \hat{c}_{i\uparrow}^\dagger \hat{c}_{j\uparrow}\rangle = \langle \hat{c}_{i\downarrow}^\dagger \hat{c}_{j\downarrow}\rangle = \frac{1}{\beta}\sum_n \mathbf{G}_{ij}^{12}(\omega_n) \qquad (11)$$

and

$$\langle \hat{c}_{i\downarrow}^\dagger \hat{c}_{j\uparrow}^\dagger\rangle = \frac{1}{\beta}\sum_n \mathbf{G}_{ij}^{11}(\omega_n), \qquad \langle \hat{c}_{i\uparrow} \hat{c}_{j\downarrow}\rangle = \frac{1}{\beta}\sum_n \mathbf{G}_{ij}^{22}(\omega_n), \qquad (12)$$

where we have summed over Matsubara frequencies ω_n. These expressions also include quantum fluctuations of the bosonic molecules when we take into account Gaussian fluctuations around the saddle-point solutions. For instance, we can integrate over these fluctuations to evaluate the correlation function

$$\langle \hat{c}_{i\alpha}^\dagger \hat{c}_{j\beta}^\dagger \hat{c}_{j'\beta} \hat{c}_{i'\alpha}\rangle - \langle \hat{c}_{i\alpha}^\dagger \hat{c}_{j\beta}^\dagger\rangle\langle \hat{c}_{j'\beta} \hat{c}_{i'\alpha}\rangle. \qquad (13)$$

In general, the Green's function $\hat{\mathbf{G}}_{ij}$ is not diagonal in space due to the presence of the fermionic tunneling $\bar{t}$ but the decay is exponential with distance $|\mathbf{R}_i - \mathbf{R}_j|$. The exponential behaviour can be approximated by taking only the diagonal part into account. In other words, in a strongly interacting Fermi gas, the formation of bosonic molecules and their dynamics is the dominant feature, and the individual tunneling of fermions is negligible. Moreover, the Green's function depends on the fields ϕ and χ. In that case, the density–density correlations reduce to

$$C_{\mathbf{r},0} = \langle \hat{n}(\mathbf{r})\rangle \delta(\mathbf{r}) + 2\left(\frac{M}{\hbar t}\right)^{2d} |\tilde{w}(\mathbf{k})|^2 |\tilde{w}(0)|^2$$
$$\times \left[-\left|\sum_i e^{i\mathbf{k}\mathbf{R}_i} \langle \hat{c}_{i\uparrow}^\dagger \hat{c}_{i\uparrow}\rangle\right|^2 + \left|\sum_i e^{i\mathbf{k}\mathbf{R}_i} \langle \hat{c}_{i\uparrow} \hat{c}_{i\downarrow}\rangle\right|^2 + \mathcal{S}(\mathbf{k}) \right]. \qquad (14)$$

The first two terms constitute the density–density correlation function for fermions [15], whereas the third and the fourth terms account for the presence of the condensed molecules. In particular, the fourth term describes the effect of quantum

fluctuations and can be expressed as a momentum distribution of the molecules [14]:

$$\mathcal{S}(\mathbf{k}) = \sum_{i,j} e^{\mathbf{k}(\mathbf{R}_i-\mathbf{R}_j)} \left(\langle \hat{b}_i^\dagger \hat{b}_j\rangle - \langle \hat{b}_i^\dagger\rangle\langle \hat{b}_j\rangle\right), \qquad (15)$$

where $\hat{b}_i^\dagger = \hat{c}_{i\downarrow}^\dagger \hat{c}_{i\uparrow}^\dagger$. Phase fluctuations can destroy these terms, for instance, in the case of a MI state of the molecules. It is important to note that fermionic terms contribute with a negative sign in equation (14), in contrast to the phase-coherent molecules, which contribute with a positive sign. This indicates a competition of the fermionic and the molecular contribution to the density–density correlation function. This provides a concept for measuring the properties of a strongly interacting Fermi gas.

5. Results

The expressions $\langle \hat{c}_{i\uparrow}^\dagger \hat{c}_{i\uparrow}\rangle$ and $\langle \hat{c}_{i\uparrow} \hat{c}_{i\downarrow}\rangle$ are constant due to translational invariance:

$$C_{\mathbf{r},0} \propto N^2 \delta_{\mathbf{k},\mathbf{G}} \left(-1 + \frac{N_0 \mathcal{N}}{N^2}\right) + \mathcal{S}(\mathbf{k}), \qquad (16)$$

where we have denoted $2N = 2\sum_i \langle \hat{c}_{i\uparrow}^\dagger \hat{c}_{i\uparrow}\rangle$ as the total number of fermions and $N_0 \mathcal{N} = \left|\sum_i \langle \hat{c}_{i\uparrow} \hat{c}_{i\downarrow}\rangle\right|^2 \propto \mathcal{N}^2 |i\phi + \chi|^2$. $\mathcal{N}$ is the number of lattice sites. The ratio $n_0 = N_0/N$ is the condensate fraction, i.e. the relative contribution of condensed molecules.

5.1. BEC

For momenta close to the reciprocal lattice vectors $\mathbf{G}$, the main contribution in the BEC comes from the term $\mathcal{S}(\mathbf{k})$ since it is singular for $\epsilon_\mathbf{k} \sim 0$:

$$C_{\mathbf{r},0} \propto \mathcal{S}(\mathbf{k}) \approx \frac{4Jn_0 + Jg_\mathbf{k}}{\epsilon_\mathbf{k}}(1 - 2g_\mathbf{k}). \qquad (17)$$

This result connects the density–density correlation function with the spectrum of the molecular condensate given in equation (6). The infrared divergence of the momentum distribution is a general property of a BEC at $T = 0$ [18]. The related 2D plot of the correlation function is shown in figure 2.

5.2. MI

For larger densities, the phase coherence in the molecular state is destroyed and a MI state with one bosonic molecule (i.e. a pair of fermions) appears. Due to strong phase fluctuations, the second term in equation (16) vanishes, and the correlation function becomes

$$C_{\mathbf{r},0} \propto -N^2 \delta_{\mathbf{k},\mathbf{G}} + \mathcal{S}(\mathbf{k}) \qquad (18)$$

with the non-singular term

$$\mathcal{S}(\mathbf{k}) \approx \frac{J^2}{4\mu^2}(1 - 2g_\mathbf{k}). \qquad (19)$$

Since the number of fermions N is large in equation (18), the contribution of $\mathcal{S}(\mathbf{k})$ is negligible in time-of-flight experiments of the MI. Thus, the MI state is characterized by sharp *dips* in contrast to the singular *peaks* in the BEC, which appear on positions corresponding to the reciprocal lattice vectors $\mathbf{G}$,
Figure 2. Density–density correlation function in units of $(\hbar t/Ma)^{-2d}$ of a strongly attractive spin-1/2 Fermi gas in an optical lattice with $J = 1$, $\mu = 0.4$ and $k_B T = 0$, where the gas forms a BEC. The number of molecules per lattice site is 0.9. The singular behaviour at the positions corresponding to the reciprocal lattice vectors is due to long-range phase coherence of the condensed molecules. There is also small modulation due to the tunneling of molecules. The axes are given in units of $\hbar t/Ma$, where a is the lattice spacing.
Figure 3. Density–density correlation function as in figure 2 but with $J = 1$, $\mu = 0.6$ and $k_B T = 0$. The number of molecules per lattice site is 1. The singular behaviour in figure 2 is replaced by dips here. This is due to the anticommuting nature of fermionic operators and thus reflects the fermionic nature of the MI state.

similar to a Bragg diffraction pattern. However, in contrast to the latter, where the diffraction pattern is created by light scattering on atoms of a crystal, here the pattern is created by the atomic state itself in the expansion process of the cloud.

Equation (19) describes the bosonic nature of the molecules in the MI state There are hole excitations in the MI phase (particle excitations are suppressed by the hard-core nature of the bosons) and their dynamics contributes to the interference pattern via the factor $\propto g_{\mathbf{k}}$. A similar situation was observed experimentally in the case of a bosonic Mott insulator in [19]. The 2D plot of the correlation function is shown in figure 3.

6. Discussion

The density–density correlation function of an expanding cloud provides a clear picture of the state when it was still trapped by an optical lattice. It consists of four different contributions in equation (14), two of which are related to the fermionic nature of the atoms. The second term leads to a fermionic dip in the density–density correlation function in the MI state. The third term measures the condensate fraction in the case of condensed bosonic molecules and together with the singular fourth term leads to the sharp peaks. Even though the third term can compete with the second term, the singular term is the most relevant in the BEC phase.

The competing behaviour of the fermionic dips and the condensate peaks in the density–density correlation function is a result of the anticommuting properties of the fermionic operators. This provides a simple concept to distinguish different states in a cloud of attractively interacting fermions. This behaviour is rather different in a bosonic cloud, where all atoms contribute with the same sign to the density–density correlation function because the bosonic operators commute [20].

In conclusion, we have studied an expanding cloud of strongly interacting spin-1/2 fermions after its release from an optical lattice. The properties are described in terms of the density–density correlation function. At lower densities a BEC is formed by the paired fermions, visible in the density–density correlation function as sharp peaks. At higher densities, a Mott-insulating phase appears, characterized by dips in the density–density correlation function. This distinct behaviour can be used in future experiments to distinguish between these two phases in a gas of strongly attractive spin-1/2 fermions in an optical lattice.
