Summary

Background. To evaluate the angioarchitecture of cerebral arteriovenous malformations (cAVMs) with special regard to its influence on the risk of intracranial haemorrhage.

Methods. Clinical and neuroradiological data of 171 patients with cAVMs, who were treated at our department, were analysed retrospectively. The angioarchitectonic data were obtained from angiographic series, cranial CT scans and MR images. A χ^2 test was conducted to correlate the parameters and determine the *P* values.

Findings. The following parameters correlate to an increased risk of haemorrhage: diameter of the nidus ≤ 2 cm ($P < 0.001$), number of arterial feeders ≤ 2 ($P < 0.001$), diameter of the main feeder ≤ 1 mm ($P < 0.0001$), number of veins draining the nidus ≤ 2 ($P < 0.001$), exclusive deep drainage ($P < 0.05$), and low or middle flow-velocity ($P < 0.01$). Specific angioarchitectonic features such as venous stenoses, varicose dilatation of the draining vein, arterial aneurysms of the feeding artery, arteriovenous fistula within the nidus, contralateral drainage and sinushypo/-aplasia did not alter the bleeding rate.

Interpretation. Various angiographic features were correlated with the occurrence of intracranial haemorrhage in patients with cerebral AVMs. In addition to the well-known factors influencing the bleeding risk of cAVMs like size, pattern of venous drainage and location within the brain our data demonstrate the importance to look at the diameter of the main feeder and the number of draining veins showing a better correlation.

Introduction

Cerebral AVMs (cAVMs) are generally regarded as congenital vascular lesions resulting from a disorder of embryonic vascular morphogenesis caused by a defect or malfunction of the embryonic capillary maturation process leading to the formation of an arteriovenous

shunt [10]. In general a cAVM consists of a feeding artery, one or more mostly dilated draining veins and a centrally located nidus. The nidus itself is a conglomerate of atypical vessels of variable diameter and wall thickness, which does not contain normal capillaries [17, 18]. In a series of 166 prospectively followed unoperated symptomatic patients with cerebral AVMs with a mean follow-up period of 23.7 years the mortality rate was 1% per year and the rate of a major rebleed was 4% per year [23]. However the natural history of an untreated cerebral AVM is difficult to assess precisely and would require prospective studies explaining the controversial discussion in the literature [3, 4, 7, 8, 13, 23, 26, 34]. The incidence of intracerebral haemorrhage associated with angioarchitectonic parameters of AVMs has been the subject of several reports, partially presenting conflicting data [3, 4, 7, 13, 14, 34]. The reason being perhaps the difficult and subjective analysis, the often only small numbers being examined and the unknown haemodynamic changes of an AVM over time and having undergone haemorrhage. The purpose of our study was therefore to determine further parameters of angioarchitecture being more powerful to predict an increased risk of intracranial haemorrhage.

Patients and methods

171 patients, the age ranging from 8 to 67 years with an average of 38 years, treated in our department were retrospectively analysed. The mean age was 36.5 years in men and 36.4 years in women with a sex

ratio of male: female of 1.19:1. Out of 171 patients, 94 were admitted to hospital due to intracranial haemorrhage including intracerebral bleeding in 59, subarachnoid haemorrhage in 16 and a combination of intracranial haemorrhage and subarachnoid haemorrhage in 18, one patient presented with a subdural haematoma. Upon admission, 136 patients had neurological deficits which depended on the site of haemorrhage, the location of the AVM or were the result of seizures. The other 35 patients had no neurological deficits.

Cranial CT scans and/or MR images were carried out in all patients. Digital subtraction angiography was performed in all patients via a transfemoral approach. In most patients superselective angiography was carried out using a co-axial microcatheter technique.

The exact localisation of the cAVMs were derived from the combined evaluation of the angiographic series, cranial CT scans and MR images. The size of the AVM was assessed as the maximal diameter of the nidus on the angiographic views. The AVMs were categorized in 5 groups, i.e. micro ($0.5 < 1$ cm), small ($1 < 2$ cm), middle ($2 < 4$ cm), large ($4 < 6$ cm) and giant AVMs (> 6 cm).

For the determination of the diameter of the feeding artery the mean was calculated from measurements taken at the origin, middle and terminal portion of the vessel on angiograms.

The haemodynamics of the cAVMs were classified into low, middle or high flow. A cAVM was considered to be of low flow if there was an early draining vein with no further change in haemodynamics. A middle-flow cAVM was characterised by early venous drainage and an entirely contrasted nidus before the appearance of regularly draining cerebral veins. High-flow AVMs presented as a reduced filling of cerebral arteries at the time of a completely contrasted nidus.

As special morphological features of cerebral AVMs aneurysms of the arterial feeder, varicose dilatations of the draining vein, arteriovenous fistulas within the nidus, venous stenoses, contralateral drainage and sinus hypo-/aplasia were evaluated and correlated with the incidence of bleeding (Table 8).

A χ^2 test was conducted for the statistical analysis of the data.

Results

Angioarchitecture of Cerebral AVMs

Localisation

Most AVMs were located in the temporal ($n = 27/15.8\%$) and frontal ($n = 26/15.2\%$) lobes (Table 1). The correlation of bleeding risk versus the localisation of the cAVM showed an increased bleeding risk for deeply and infratentorially located AVMs, such as the basal ganglia/thalamus (12 out of 16 had bled, 75%), corpus callosum (8 out of 8 had bled, 100%), hippocam-

Table 1. Localisation of the AVMs

Localisation	Number of patients	Percentage
Frontal	26	15.2
Frontoparietal	16	9.4
Frontotemporal	8	4.7
Temporal	27	15.8
Temporoparietal	8	4.7
Temporooccipital	3	1.8
Occipital	17	9.9
Parietooccipital	9	5.3
Parietal	16	9.4

pus (2 out of 3 had bled, 67%) or cerebellum (12 out of 13 had bled, 92%).

Size

According to their maximal diameters, cerebral AVMs were classified into five groups. 16 (9.4%) AVMs were microangiomas ($0.5 \leq 1$ cm), 27 (15.8%) were small AVMs ($1 \leq 2$ cm), 88 (51.5%) were middle sized AVMs ($2 \leq 4$ cm), 29 (17.0%) were large ($4 \leq 6$ cm) and 11 (6.4%) were giant AVMs (> 6 cm). Small and microangiomas had a much higher bleeding risk (35/43, $P < 0.001$) than larger ones (Table 2). 57 of the 117 middle sized and large AVMs had bled (48.7%), however 9 out of 11 giant AVMs suffered no bleeding (81.8%). No correlation could be found between the size of the AVM and the diameter of its feeding artery or its draining vein.

Arterial supply

Out of the 171 AVMs 51 (29.8%) were supplied by one or two arteries, 52 AVMs (30.4%) by three or four

Table 2. Incidence of haemorrhage depending on the size (max. diameter) of the nidus

Size of the nidus	Haemorrhage	No haemorrhage	Total	p-value
Microangiomas ($0.5 \leq 1$ cm)	13	3	16 (9.4%)	$p < 0.001$
Small AVMs ($1 \leq 2$ cm)	22	5	27 (15.8%)	$p < 0.001$
Middle sized AVMs ($2 \leq 4$ cm)	42	46	88 (51.5%)	
Large AVMs ($4 \leq 6$ cm)	15	14	29 (17.0%)	
Giant AVMs (> 6 cm)	2	9	11 (6.4%)	
Total	94 (55.0%)	77 (45.0%)	171 (100%)	

arteries and 68 AVMs (39.8%) by five or more arteries, the highest being 18 arteries. AVMs with 2 or less feeding arteries had a significantly higher incidence of bleeding, i.e. 17 out of 34 had bled ($P < 0.001$, Table 3).

In addition to the number of arterial feeders the diameter of the main feeder proved itself to be a highly important criterion. The mean diameter of the feeding arteries varied between 0.5 to 3.5 mm, one measuring 4 mm. 93 out of 171 AVMs (54.4%) had feeding arteries with a diameter between 1.1 and 2.0 mm, whereas 28 out of 171 (16.4%) lay between 0.5 and 1.0 mm and 49 out of 171 (28.7%) between 2.0 and 3.5 mm. There was a significantly increased bleeding risk for AVMs with feeding arteries less or equal to 1.0 mm of diameter. 26 out of 28 cerebral arteriovenous malformations (93%) had bled ($P < 0.0001$, Table 4).

Venous drainage

90 out of 171 cerebral AVMs (52.6%) were drained by superficial veins, whereas 22 AVMs (12.9%) showed a

drainage by deep veins and 59 AVMs (35.5%) by both. Out of the 22 AVMs drained by deep veins 18 (81.8%) had bled ($P < 0.05$). However AVMs with a predominantly superficial or mixed venous drainage showed no increased bleeding risk (Table 5).

The number of draining veins varied between one and nine for the cortical veins and between one and three for the deep veins and showed a correlation with the size of the AVMs. AVMs with a diameter of more than 4 cm had a higher number of draining veins, whereas about 80% of the AVMs up to 2 cm had no more than 2 draining veins. For these AVMs with only one or two draining veins a highly significant increase of intracranial bleeding was found ($P < 0.001$). Out of 77 AVMs with two or less draining veins 55 (71.4%) had bled (Table 6).

Haemodynamics

According to their haemodynamic characteristics on angiograms, cerebral AVMs were divided into low-flow, mid-flow and high-flow AVMs. Most cerebral AVMs (133/171, 77.8%) were high-flow lesions,

Table 3. Correlation between the number of arterial feeders and the incidence of haemorrhage

Number of arterial feeders	Haemorrhage	No haemorrhage	Total	<i>p</i> -value

Total	94 (55.0%)	77 (45.5%)	171 (100%)	

Table 6. Incidence of haemorrhage depending on the number of draining veins

Number of draining veins	Haemorrhage	No haemorrhage	Total	<i>p</i> -value
1–2 Veins	55 (71.4%)	22 (28.6%)	77 (45.0%)	<i>p</i> < 0.001
3–4 Veins	21 (40.4%)	31 (59.6%)	52 (30.4%)	
5–9 Veins	18 (42.9%)	24 (57.1%)	42 (24.6%)	
Total	94 (45.0%)	77 (55.0%)	171 (100%)	

Table 7. Correlation between the incidence of haemorrhage and the flow-velocity

Flow-Velocity	Haemorrhage	No haemorrhage	Total	<i>p</i> -value
High-flow	65 (48.9%)	68 (51.1%)	133 (77.8%)	<i>p</i> < 0.01
Middle-flow	24 (72.7%)	9 (27.3%)	33 (19.3%)	
Low-flow	5 (100%)	0	5 (2.9%)	<i>p</i> < 0.01
Total	94 (55.0%)	77 (45.0%)	171 (100%)	

whereas 33 (19.3%) were mid-flow and only 5 (2.9%) were low-flow lesions. The correlation between the flow velocity and the incidence of bleeding revealed that all low-flow AVMs (5/5) and the majority (24/33) of mid-flow AVMs had bled. On the contrary, there was no significant increase of bleeding in high-flow AVMs ($P < 0.01$, Table 7). The low-flow AVMs were less or equal to 2 cm in size, whereas the mid-flow AVMs ranged from 5 mm to 41 mm, about 75% lying between 2–4 cm.

Specific angioarchitecture

21 out of 171 patients (12.3%) showed an arterial aneurysm of the feeding artery (Fig. 1) and two patients showed two arterial aneurysms. 13 out of these 23 patients (56.5%) had bled reaching no statistical significance (Table 8). All these aneurysms were located at the feeding arteries close to the nidus and differed greatly in size.

Varicose dilatation of the draining vessel was found in 57 AVMs (33.3%), out of which 24 (42.1%) had bled

Fig. 1. Supraselective angiography of a parietal arteriovenous malformation with a saccular aneurysm

Table 8. Incidence of haemorrhage depending on certain morphological features

Angioarchitecture	Presence of the morphological feature (n = 171)	Incidence of haemorrhage within its group
Aneurysms	23 (13.5%)	13 (56.5%)
Art.-ven. fistulas	101 (59.1%)	50 (49.5%)
Steal-effects	75 (43.9%)	32 (42.7%)
Varicose dilatation	57 (33.3%)	24 (42.1%)
Venous stenosis	67 (39.2%)	35 (52.2%)
Contralateral drainage	20 (11.7%)	11 (55.0%)
Sinushypo/-aplasia	6 (3.5%)	4 (66.7%)

Fig. 2. Varicose dilatation of an arteriovenous malformation of the posterior choroidal artery

(Table 8, Fig. 2), showing a tendency towards a reduction of the bleeding risk.

A stenosis of the draining vein was found in 67 cases (39.2%). The stenosis could be located anywhere along the vessel, but the majority lay at the proximal portion of the draining vessel. In some cases the stenosis was found at the entrance of veins into the sinus, esp. at the Galenic point (Fig. 3). The number of stenotic draining veins per AVMs varied between one and four. 55 AVMs had only one venous stenosis, whereas nine AVMs had two, two

Fig. 3. Lateral view of a deeply located arteriovenous malformation demonstrating a stenosis of the draining vein at the Galenic point

AVMs had three and one AVM had four stenosis. However, the relationship between the number of venous stenosis and the incidence of bleeding did not reveal any statistically significant change of bleeding risk. The distance of the stenosis from the nidus and the incidence of bleeding was not statistically significant either.

In 101 cases (59.1%) fistulae were demonstrated within the nidus, although neither an increased nor a lowered bleeding risk related to the fistula could be found (Fig. 4).

Fig. 4. Left: Angiogram of left internal carotid artery lateral view with a temporo-parietal arteriovenous malformation. Right: Supraselective angiography demonstrating the angioarchitecture with intranidal fistulas and early drainage into cortical veins

The evaluation of contralateral drainage of the cAVM present in 20 cases (11.7%) as well as a sinushypo/aplasia present in 6 cases (3.5%) did not alter the risk for intracranial haemorrhage (Table 8). However for sinushypoplasia or sinusaplasia this may only be due to small numbers since 4 out of 6 AVMs bled suggesting a tendency towards an increased bleeding risk.

Discussion

The standard categorisation of arteriovenous malformations from a surgical point of view involves the Spetzler-Martin grading system [28], which uses a simple analysis of size, location and venous drainage. For the risk of intracranial haemorrhage the location of the cAVM seems to play a dominant role. In the recent literature Turjman *et al.* [31] showed a higher incidence of bleeding, when the AVM was located in the basal ganglia and Mansmann found a correlation with AVMs in the corticocallosal and posterior fossa location [13]. In our study out of 16 AVMs in the basal ganglia 12 (75%) had caused intracranial haemorrhage supporting these findings and moreover an increased rate of haemorrhage could be shown for all AVMs located deeply or infratentorially, i.e. AVMs of the basal ganglia, corpus callosum, hippocampus and cerebellum. Besides the localisation other responsible factors for this increase of associated bleeding may include the presence of additional risk factors, such as stenosis of the vein of Galen or short feeding arteries with high pressure in these deeply located AVMs.

The classification of cAVMs according to their sizes varies in the literature [28, 31]. In our study we choose the category of >6 cm following the Spetzler – Martin grading system, the other AVMs were placed in 4 subgroups (i.e. micro, small, middle, large) instead of 2 subgroups (<3 cm, 3–6 cm) to obtain a more accurate discrimination concerning the risk of haemorrhage. About 50% of the AVMs belonged to the middle-sized group, whereas 25% belonged to either the smaller or the larger groups. Within the two groups of micro and small AVMs a significantly increased bleeding risk was found compared to middle, large and giant AVMs. Out of the 43 AVMs with small volumes 35 (81.4%) had bled ($P < 0.001$). Giant AVMs with a maximal diameter of more than 6 cm showed a significantly decreased incidence of bleeding. These results are in accordance with the findings in the literature [1, 4, 9, 10, 12, 24, 25, 27, 29] and, keeping in mind the limitations of a retrospective analysis not representing the natural history of

AVMs, it can be assumed that the 171 patients in our study give a representative picture of symptomatic cAVMs.

Looking at the number of arterial feeders we found a highly significant correlation: AVMs with more than five feeding arteries had a lower bleeding risk and those with maximally two arterial feeders had a higher bleeding risk ($P < 0.001$). This result could be due to a correlation between the size of the nidus and the number of arterial feeders, since two-thirds of the AVMs less than 2 cm in diameter were supplied by only one or two feeding arteries.

AVMs with a feeding artery of maximal 1.0 mm of vessel diameter showed a markedly increased bleeding risk ($P < 0.0001$). To our knowledge this parameter has not been looked at in the past, however its consideration could play a major role for the estimation of the risk of haemorrhage and should be investigated more thoroughly in a prospective trial. A potential explanation for this phenomenon could be the decline of pressure within the feeder which increases with a smaller diameter, which is consistent with the law of Hagen-Poiseuille.

Impairment of the venous drainage has previously been described to play a major role for an increased rate of haemorrhage [7, 9, 23]. In our study we found that 55 out of 77 cAVMs (71.4%) with up to two draining veins had bled ($p < 0.001$). In contrast Vinuela [33] did not confirm this correlation between the number of draining veins and the incidence of bleeding, however our data are in agreement with the findings by Albert [1] in 150 patients. On the other hand cerebral AVMs with five or more draining veins showed a lower bleeding risk. The reason could be a better outflow of the blood from the nidus correlating with a lower intranidal pressure. In contrast in case of a limited draining system, possibly the pressure within the nidus and its feeding and draining vessels rises and vessel rupture may result. This hypothesis is supported by the findings of Nornes and Grip [22], who reported that the mean venous pressure in the nidus region is 17 mmHg in patients with an AVM with bleeding and 14 mmHg in patients with an AVM without bleeding and by Spetzler *et al.* [29], who measured the vascular pressure intra-operatively. We assume therefore that the intravascular pressure within the nidus and its related veins is a decisive factor concerning the bleeding risk.

The relevance of superficial or deep venous drainage of cerebral AVMs has been examined in several studies [5, 13, 15, 20, 31, 33] and has been regarded as an

important risk issue. Our data stress further the major role of this risk factor, since 18 out of 22 AVMs (81.8%) with pure deep venous drainage had bled, whereas AVMs with superficial or mixed drainage showed no increased incidence of bleeding.

In this study venous stenoses were demonstrated in 67 AVMs (39.2%) both in the cortical and deep draining veins. Stenosis in deep cerebral veins was most frequently located in the vein of Galen. Vinuela [33] studied 53 deep brain AVMs and found a stenosis in the vein of Galen in 14 AVMs and occlusion in the inner draining system in 7 AVMs. Their formation could be based upon the anatomical particularity of this draining system. The venous blood from the deep white substance, basal ganglia, corpus callosum, third and fourth ventricles gathers in the region of the Galenic system and drains into only one vein. This causes marked haemodynamic changes including a change from laminary to turbulent blood flow, which can cause endothelial injury and subsequent thrombotic occlusion or vessel stenosis [6]. By intra-operative Doppler sonography Nornes and Grip [22] showed, that a turbulent flow and an increased intravascular pressure could produce shearing stress with endothelial destruction and, consecutively, a secondary thrombosis. The degree of stenosis in the present study varied between 20% and 90%. Four out of 5 AVMs with more than 80% stenosis of a draining vein presented with intracranial haemorrhage. This increased incidence of bleeding is in agreement with previous studies and is presumably due to proximal venous hypertension. In our patients most stenoses lay 3 to 4 cm distal to the nidus and there was no post-stenotic dilation in the cortical draining veins. However, Albert [1] considered venous stenosis an anatomical variation or due to angiographic projection.

In the present study contrary to venous stenosis an ectatic dilatation of a draining vein showed a tendency towards a lower bleeding risk but did not reach statistical significance. This finding is discussed controversially in the literature. Nataf *et al.* [21] found a weak positive correlation of venous ectasia and a higher incidence of bleeding, whereas Mansmann [13] described a lower rate of ICH. However, our results are in good agreement with the findings of Turjman *et al.* [31], who did not find any correlation. The cause for these discrepancies could lie in the missing detailed analysis in how many cases the venous ectasia was associated with an adjacent stenosis. Valavanis *et al.* [32] describe a varix formation proximal to a high-grade stenosis of draining veins being a predisposing factor of AVM rupture. Therefore in

combination with a stenosis the risk for haemorrhage may increase, whereas a venous dilatation by itself may well be associated with a lower bleeding risk, since it may act as a buffer zone.

The association of arterial aneurysms with cerebral AVMs has been widely studied. The reported incidence of such aneurysms varies greatly from 2.7% to 23% with an average of about 10% [2, 11, 19, 26, 35, 36]. In recent studies using superselective angiography, Turjman [30] found the incidence of such aneurysms being as high as 58%. In our study arterial aneurysms in the feeding artery were found in 23 AVMs (13.5%), the lower prevalence being possibly explained by the fact, that not all of our diagnostic angiographies were performed superselectively. However, the finding of a tendency towards an increased risk for haemorrhage with 57% of these AVMs having bled is in good agreement with the literature [2, 14, 16, 35].

In 101 AVMs (59.1%) arteriovenous fistulas were found in the nidus out of which 50 (49.5%) had bled. An increased risk of haemorrhage could not be demonstrated in these AVMs, which is in agreement with Willinsky *et al.*, who reported a 40% incidence of bleeding in AVMs with this characteristic [35].

Another aspect studied in our patients was the correlation of flow-velocity and bleeding risk. 133 AVMs (77.8%) were high-flow, 33 (19.3%) were mid-flow and 5 (2.9%) were low-flow AVMs. Lesions with high-flow had no increased incidence of bleeding. On the contrary, all low-flow and 29 of the 38 mid-flow AVMs (76.3%) had bled. A possible explanation is the higher intravascular pressure due to the delayed venous blood drainage as well as the fact, that low flow-velocities were only present in small and micro AVMs and middle flow-velocities mainly in small and middle AVMs and these have per se a higher tendency to bleed.
