One of the most promising technologies for the fabrication of high-$T_c$ cables is the ion-beam-assisted deposition (IBAD) technique. The performance of the superconductors fabricated by IBAD, and the fabrication costs, are to a great extent determined by the critical current densities of the superconductors’ grain boundaries. Since, in bicrystalline samples, overdoping has been found to improve the transport properties of grain boundaries in high-$T_c$ superconductors, we have explored whether overdoping also enhances the critical currents of IBAD samples. The measurements show that, depending on the critical current density of the superconducting film, $J_c$ (77 K) is increased by factors up to 2.2, also in applied magnetic fields of several tesla. © 2003 American Institute of Physics. [DOI: 10.1063/1.1543640]

The most promising approaches to the fabrication of competitive cables from high-$T_c$ superconductors operating at 77 K are the coated conductor technologies. These technologies aim to avoid the deleterious effects of large angle grain boundaries on the critical current density $J_c$, by aligning the grains to a few degrees along all major crystal axes. Large efforts have been undertaken to develop practical technologies for the fabrication of polycrystalline high-$T_c$ superconductors with well aligned grains, of which the ion-beam-assisted deposition (IBAD), the rolling assisted biaxially textured substrate process, and the inclined substrate deposition technique are the most advanced. By using these processes $J_c$ values well above $10^6$ A/cm$^2$ have been achieved for conductors up to several meters in length. The required precise alignment of the grains, however, is still a costly and time consuming procedure.

We have shown recently that the critical current density of grain boundaries can be increased by appropriate doping, for example by doping YBa$_2$Cu$_3$O$_7$-d with Ca. The increase of $J_c$ achieved by doping is maintained at temperatures up to $T_c$ if the doping is performed by employing doping heterostructures. These experiments suggest to use doping also to improve coated conductors. To explore whether this is possible, we measured the effects of the doping on the critical current densities of YBa$_2$Cu$_3$O$_7$-d based IBAD samples.

For these experiments, we used YSZ polycrystalline substrates covered with an IBAD YSZ layer and a 20-nm-thick Y$_2$O$_3$ buffer layer, fabricated by Siemens in a standard process. To assess the quality of the substrates they were coated with 700-nm-thick YBa$_2$Cu$_3$O$_7$-d layers, of which $J_c$ was measured. The YBa$_2$Cu$_3$O$_7$-d layers were then removed by etching and the substrates were transferred to the University of Augsburg.

On the Y$_2$O$_3$ covered substrates 160-nm-thick YBa$_2$Cu$_3$O$_7$-d films were grown by pulsed laser deposition from YBa$_2$Cu$_3$O$_7$-d targets. After deposition at 760 °C the samples were cooled within one hour to 400 °C in oxygen atmosphere of 0.4 bar and, after holding this temperature for 20 min, further to room temperature.

The critical current densities of one group of the samples were then measured inductively. To dope the samples, 20-nm-thick Y$_{0.7}$Ca$_{0.3}$Ba$_2$Cu$_3$O$_7$-d cap layers were subsequently deposited on these samples by pulsed laser deposition under the conditions given earlier. After doping, $J_c$ was measured again. The inductive $J_c$ measurements were performed using the self-inductance method described in Ref. 15. In this technique, steadily increasing ac-screening currents are magnetically induced in the sample by a drive current $I_d$ flowing through a coil placed on top of the sample. The magnetic fields generated by these currents are picked up with the same coil. The detection of the drive frequency’s third harmonic signals that the density of the screening currents exceeds the critical current density of the superconducting film.

For control purposes another group of samples was characterized by transport measurements. These samples were patterned by photolithography and wet etching into standard four-point configurations with 30 μm wide and 200 μm long bridges. After measuring $J_c$, using a 1 μV criterion, the gold contacts were removed by ion etching. Subsequently a 20-nm-thick Y$_{0.7}$Ca$_{0.3}$Ba$_2$Cu$_3$O$_7$-d cap layer was grown on these samples too, before the samples were again patterned to regain the original bridges.

A typical result of the inductive $J_c$ measurements is shown in Fig. 1, in which the amplitude of the third har-
monic signal is plotted as a function of \( I_d \) for a standard IBAD sample. As illustrated by this figure the critical current density of this sample was enhanced by doping by a factor of 1.4. This increase of \( J_c \) by doping is characteristic for the behavior of the whole set of samples we have studied. The samples furthermore revealed a characteristic trend: the \( J_c \) values of the samples with small critical current densities were increased by larger factors than the critical current densities of the samples which already had high \( J_c \) values before doping. This is illustrated by Fig. 2, in which for all inductively investigated samples the doping induced enhancement of \( J_c \) is plotted as a function of the critical current density measured prior to the doping on the 700-nm-thick YBa\(_2\)Cu\(_3\)O\(_7\) films. Whereas no increase was observed on the substrate with the best texture, enhancement factors in the range of 1.4–2.2 were obtained on all other samples.

The doping induced enhancement of the IBAD samples’ critical current densities was confirmed by the transport measurements. Figure 3 shows as an example the temperature dependence of the critical current density of one bridge of an IBAD sample before and after doping. Clearly, \( J_c \) is enhanced in the whole temperature range up to \( T_c \), at 77 K by a factor of 1.5, as also illustrated by the inset of Fig. 3, which depicts the \( I-V \) curves of a bridge before and after doping. Doping also increased the \( n \) value of the sample, as obtained from the \( I-V \) characteristics in the range of 10–100 \( \mu \)V. It equalled \( \approx 15 \) and \( \approx 25 \) for the undoped and doped sample, respectively. Like the inductive measurements, the transport experiments revealed the largest \( J_c \) enhancements for the samples with small critical current densities (see inset of Fig. 2). This behavior is consistent with earlier measurements which showed that the doping induced \( J_c \) enhancement increases with increasing grain boundary angle, i.e., with decreasing critical current density of the samples.\(^4\)

To analyze whether doping also improves the critical current density of IBAD samples in magnetic fields \( H \), the \( J_c(H) \) characteristics of three samples were measured at 77 K by transport in magnetic fields up to 8 T applied parallel to the tape normal. The samples showed a similar behavior, and the result of one sample is plotted in Fig. 4. As shown, the \( J_c \) enhancement is found in the whole magnetic field range, and even increases considerably in fields exceeding 6 T. This effect is attributed to a shift of the irreversibility line due to a slight enhancement of \( T_c \) after doping. A comparable large doping induced \( J_c \) enhancement at 8 T was observed by Yao et al.\(^{16}\) on 5-\( \mu \)m-thick YBa\(_2\)Cu\(_3\)O\(_{7}\) films. In our case, the
samples that had retained their $T_c$ after doping did not show the very large enhancement in high magnetic fields, but an almost constant $J_c$ increase over the whole field range.

In summary, the use of doping heterostructures was found to enhance the critical current density of conventional coated conductors. By doping, the critical current density of the investigated IBAD tapes was enhanced by factors as large as 2.2, at all temperatures up to $T_c$. At 77 K, the $J_c$ enhancement persists in magnetic fields of at least 8 T.
