(Received 24 January 2000)

The phase diagram of BaVS<sub>3</sub> is studied under pressure using resistivity measurements. The temperature of the metal to nonmagnetic Mott insulator transition decreases under pressure, and vanishes at the quantum critical point  $p_{cr} = 20$  kbar. We find two kinds of anomalous conducting states. The high-pressure metallic phase is a non-Fermi liquid described by  $\Delta\rho \propto T^n$  where  $n = 1.2-1.3$  at  $1 < T < 40$  K. At  $p < p_{cr}$ , the transition is preceded by a wide precursor region with critically increasing resistivity which we ascribe to the opening of a soft Coulomb gap.

Understanding the Mott transition, and clarifying the nature of the phases on either side of the transition, is of great importance. Though metal-insulator transitions are often accompanied by an ordering transition and/or influenced by disorder, one may speak about a “pure” Mott transition which is a local correlation effect in an ideal lattice system, and takes place without breaking any global symmetry. Many aspects of this problem can be studied on the multifaceted behavior of BaVS<sub>3</sub> [1–3].

The metal-insulator transition of the nearly isotropic 3D compound BaVS<sub>3</sub> offers a realization of the pure Mott transition in nature [3]. Under atmospheric pressure BaVS<sub>3</sub> has three transitions: the hexagonal-to-orthorhombic transition at  $T_S = 240$  K which has only a slight effect on the electrical properties; the metal-insulator transition at  $T_{MI} = 69$  K, which does not seem to break any of the symmetries of the metallic phase; and the ordering transition at  $T_X = 30$  K [4]. In spite of decades of effort, the character of the phases and the driving force of the transitions at  $T_{MI}$  and  $T_X$ , remain mysterious.

Here we report the results of single crystal resistivity measurements under hydrostatic pressure in the range of  $1 \text{ bar} \leq p < 25$  kbar. These pressures encompass the entire insulating phase and part of a high-pressure low- $T$  conducting phase. We report the first observation of the quantum critical point in BaVS<sub>3</sub>, and we characterize the strange metallic phase lying beyond the critical pressure  $p_{cr}$ . On the metallic side of the phase boundary, we identify two regimes with anomalous properties: (i) a broad region at  $p < p_{cr}$  in which the resistivity increases strongly with decreasing temperature, and (ii) a high-pressure non-Fermi-liquid state.

Single crystals of BaVS<sub>3</sub> were grown by tellurium flux method. The crystals, obtained from the flux by sublimation, have typical dimensions of  $3 \times 0.5 \times 0.5 \text{ mm}^3$ . The resistivity was measured in four probe arrangement. The current was kept low enough to avoid the self-heating of the sample. For the high-pressure measurements the crystal was inserted into a self-clamping cell with kerosene as a pressure medium. The pressure was monitored *in situ* by

an InSb sensor. During cooling down the cell there was a slight pressure loss, but its influence on the temperature dependence of the resistivity was negligible. Above about 15 kbar the pressure was stable within 0.1 kbar in the whole temperature range.

Figure 1 shows the temperature dependence of the resistivity for various pressures. As expected from earlier low-pressure data [1],  $T_{MI}$  decreases smoothly with increasing pressure. The linear plot highlights the contrasting behavior of  $\rho(T)$  below and above the critical pressure, but does not include the regime of higher resistivities. Part of this is shown in the logarithmic plot of Fig. 2; it can be perceived that the overall resistivity change at the transition

FIG. 1. Temperature dependence of the resistivity  $\rho(T)$  for various pressures. The  $T = 0$  insulator-to-metal transition sets in at  $p_{cr} \approx 20$  kbar.

FIG. 2. Upper panel: temperature dependence of the resistivity  $\log\rho(T)$  for various pressures. Lower part:  $d\log\rho/d(1/T)$  for selected pressures. The spikes define the metal-insulator transition temperatures.

remains roughly the same, though  $T_{\text{MI}}$  is suppressed. The pressure dependence of the metal-insulator transition temperature was determined from the spikes of the logarithmic derivative,  $d(\log\rho)/d(1/T)$ , as shown in the lower panel of Fig. 2. The narrowness of the spikes indicates that the transition remains sharp under pressure. For  $p = 19.8$  kbar we still found a metal-insulator transition at  $T_{\text{MI}} \approx 5.6$  K, but for 21.4 kbar, the resistivity keeps on decreasing at least down to 1 K. We estimate that  $p_{\text{cr}} \approx 20$  kbar. The phase boundary is shown in Fig. 3. Our resistivity measurements allow the division of the conducting phase into further regions of markedly different nature; the discussion of these follows.

For  $p < p_{\text{cr}}$  the resistivity in the metallic phase has a marked minimum at  $T_{\text{min}}(p)$  preceding the metal-insulator transition. Finding  $d\rho/dT < 0$  in a metal is anomalous, and it is tempting to regard the interval  $T_{\text{MI}} < T < T_{\text{min}}(p)$  as an extended precursor regime to the insulating phase. As shown in Fig. 3 by the dashed line,  $T_{\text{min}}$  drops to zero simultaneously with  $T_{\text{MI}}$ : the insulator and its precursor vanish together. We argue that the resistivity minimum is a collective effect: if it were due to impurities, it would have no reason to disappear beyond  $p_{\text{cr}}$ , but in fact its appearance is contingent upon the existence of the Mott insulator phase.

BaVS<sub>3</sub> is essentially an isotropic 3-dimensional system [3], thus the appearance of a wide precursor regime within the metallic phase is not a regular feature. There is, how-

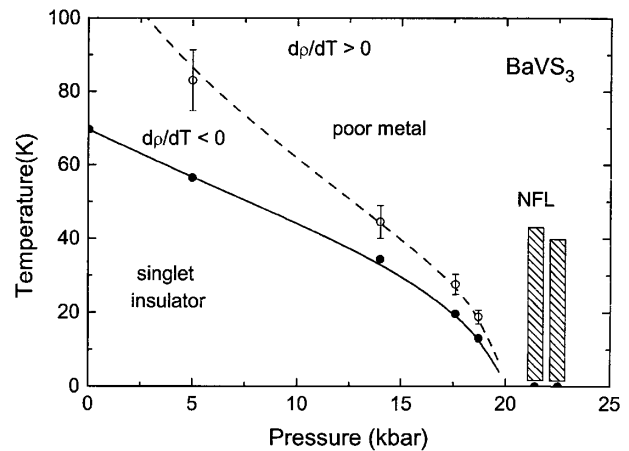

FIG. 3. The  $p$ - $T$  phase diagram of BaVS<sub>3</sub> on the basis of resistivity measurements. Solid line: metal-insulator phase boundary; dashed line: the boundary of the precursor region. The columns indicate the range of the non-Fermi-liquid  $\Delta\rho \sim T^n$  law.

ever, an interesting subclass of Mott systems to which it is common: e.g., similar behavior is seen above the Verwey transition in magnetite [5,6]. The  $T_{\text{min}}(p)$  line is not a phase boundary; it merely marks the onset of strong fluctuations towards a gapped state. The Hall results on polycrystalline BaVS<sub>3</sub> [2] imply that the number of carriers may change in this temperature range: we believe that resistivity enhancement arises from the loss of charge carriers. A similar phenomenon is observed in Fe<sub>3</sub>O<sub>4</sub>, where increasing charge short range order results in a diminishing effective number of carriers, and a resistivity minimum [6].

It is remarkable that the apparent opening of a soft charge gap is not accompanied by the opening of a spin gap; the magnetic susceptibility does not show any noticeable anomaly at  $T = T_{\text{min}}$  [3]. This suggests that the phenomenon which sets in at  $T_{\text{min}}$  is quite distinct from the opening of a real gap which happens at  $T_{\text{MI}}$ . We note that a somewhat similar scenario, but with particular emphasis on possible 1D aspects, was considered in [2]. However, the essentially isotropic conductivity [3] rules out 1D interpretations.

The resistivity data suggest that the insulating state is approached through a regime of critically increasing resistivity. There are precedents that valuable insight can be gained by trying to identify apparently critical behavior in transport data [7]. Power law behavior can be demonstrated by plotting the resistivity,  $\rho(t)$ , as a function of the reduced temperature on logarithmic scales [ $t = (T - T_{\text{MI}})/T_{\text{MI}}$ ]. The ambient pressure result is shown in Fig. 4: the power law  $\rho \propto t^{-0.4}$  gives a good approximation over more than 30 K above  $T_{\text{MI}}$ , over almost 2 decades in the reduced temperature,  $t$ .

Phenomenologically, low-pressure BaVS<sub>3</sub> can be related to other (essentially 3D) systems which share at least some of its features: the existence of the intermediate disordered

FIG. 4. The logarithmic plot of the resistivity vs reduced temperature. The resistivity follows a power law in a substantial part of the interval  $T_{MI} < T < T_{min}$ .

insulating phase, the resistivity precursor, and the lack of a discernible Fermi edge in XPS spectra [8]. In addition to magnetite [5,6] we mention  $\text{Ca}_2\text{RuO}_4$  [9], and  $\text{Ti}_4\text{O}_7$  [5]. The detailed behavior of either of these systems is quite different from that of  $\text{BaVS}_3$ , but we believe that there is also a common feature: the soft Coulomb gap due to short-range charge fluctuations.

Next we discuss the high-pressure metallic phase. Figure 5(a) reveals that the temperature dependence of the resistivity is characteristic of a bad metal [10]. The high-temperature behavior is sublinear, and though  $\rho(T = 300 \text{ K})$  corresponds to a mean free path  $l \sim 5\text{--}8 \text{ \AA}$ , which is of the order of the lattice constant,  $\rho$  continues to grow without any sign of saturation. It has been shown that strong electron-phonon scattering could account for such a behavior [11], but we believe that in our case the electron-electron scattering dominates. This assumption is supported by the specific heat data [12]: the electronic (primarily orbital) entropy keeps on increasing even beyond 300 K. The magnitude and the unusual shape of  $\rho(t)$  indicate a new scattering process, which is to be associated to orbital fluctuations.

The low temperature region of the pressure-induced metallic phase is particularly interesting. For  $T < 40 \text{ K}$  the resistivity does not follow the characteristic Fermi liquid behavior  $\Delta\rho = \rho(T) - \rho_0 \propto T^2$  ( $\rho_0$  being the residual resistivity); instead, it appears to be described by a power law  $\Delta\rho \propto T^n$  with  $1 \leq n < 2$ . To find out about this possibility, it is customary to plot  $d \log \Delta\rho / d \log T$  versus  $T$  and check whether it has a plateau [13]. We show such a plot as Fig. 5(b).  $d \log \Delta\rho / d \log T$  is approximately constant from low temperatures up to  $T \approx 40 \text{ K}$ , allowing one to fit the resistivity with the non-Fermi-liquid “law”  $\Delta\rho \propto T^{1.25}$  at  $p = 22.5 \text{ kbar}$  [Fig. 5(c)]. We have similar results for  $p = 21.4 \text{ kbar}$ , where  $\Delta\rho \propto T^n$  holds with  $n \approx 1.2$ . The extent of the non-Fermi-liquid regime is given by columns in Fig. 3.

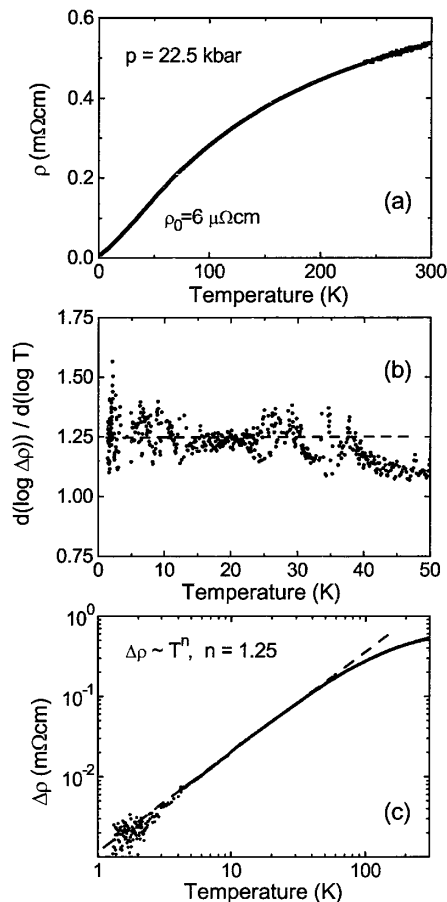

FIG. 5. The temperature dependence of the resistivity at  $P = 22.5 \text{ kbar}$ . (a)  $\rho$  on linear scales, (b)  $d \log \Delta\rho / d \log T$  vs  $T$ , and (c)  $\Delta\rho = \rho - \rho_0$  on logarithmic scales.

The above low temperature behavior is similar to that of nearly antiferromagnetic  $f$ -electron systems such as  $\text{CePd}_2\text{Si}_2$  [14]. The interpretation usually invokes nearness to a quantum critical point, or the existence of rare regions [13,15]. In these cases the non-Fermi-liquid region is placed into a phase diagram where the static properties of the phases are in principle well understood. It is not so with  $\text{BaVS}_3$  for which there is no consensus either about the driving force of the metal-insulator transition, or the nature of the low- $T$  phases. Since even weak extrinsic disorder can have a drastic effect on the critical behavior, the relative importance of correlation and disorder has to be assessed both for the insulator and the various conducting regimes.

The effects of the vicinity of a ferromagnetic, or an antiferromagnetic, quantum critical point on the metallic resistivity have been worked out [13]. The overall appearance of the susceptibility curve [3] shows that  $\text{BaVS}_3$  is dominated by antiferromagnetic spin-spin interactions, so the predictions concerning the resistivity of a nearly antiferromagnetic metal are relevant. It has been argued that for samples of sufficiently good quality,  $\Delta\rho \propto T^n$  where  $n < 1.5$ , and finding  $n = 1.2\text{--}1.3$  over 1–2 decades of

$T$  is a reasonable expectation [16]. This is in full accordance with our results. The fact that at  $p = 22.5$  kbar  $\rho_{300}/\rho_0 \sim 100$ , shows that our sample is of good quality and disorder effects are weak as far as the high-pressure conductor is concerned.

We note that  $\text{CaRuO}_3$  provides another example of a  $d$ -electron system whose non-Fermi-liquid nature is probably explained by its being nearly antiferromagnetic. However, its resistivity follows the  $\Delta\rho \propto T^{1.5}$  relationship [17], which is expected for dirty samples [16].

The reason for the lack of magnetic long range order in the  $T_X < T < T_{\text{MI}}$  insulating phase is not evident. One may first think that the in-plane frustration is responsible because the V ions form triangular  $a$ - $b$  planes. However, neither the isotropic nor the anisotropic triangular Heisenberg model is frustrated enough to give a spin liquid [18]. One may be tempted to invoke disorder: it is known that quantum antiferromagnets (especially for  $S = 1/2$ ) tend to be unstable against the formation of a random singlet phase [19]. However, the issue of the effect of quenched weak disorder is still open.

We believe that in a weakly frustrated system like  $\text{BaVS}_3$ , the Heisenberg model would order, and  $\text{BaVS}_3$  is nonmagnetic because its effective Hamiltonian is not a pure Heisenberg model. We argued that including the orbital degrees of freedom of the low-lying crystal field quasidoublet, one finds a large number of energetically favorable dimer coverings of the triangular lattice such that intradimer spin coupling is strong, while interdimer perturbations are weak [3]. The equilibrium phase at  $T_X < T < T_{\text{MI}}$  can be visualized as a thermal average over a class of valence bond solid states. Intradimer interaction causes the opening of a spin gap, while interdimer interactions give rise to intermediate-range correlation, and a  $\mathbf{Q}$  dependence in the spin excitation spectrum [20]. We do not have to invoke disorder to explain the singlet phase. Experimentally, either off-stoichiometry [21] or Ti doping [22] is known to break up singlet pairing. The well-developed singlet insulating phase is the hallmark of a clean system.

In conclusion, we studied the phase diagram of the non-magnetic Mott system  $\text{BaVS}_3$  by resistivity measurements. A quantum critical point  $p_{\text{cr}} \approx 20$  kbar was found, and the results revealed the existence of anomalous conducting regimes. The pressure-induced metallic phase is a non-Fermi-liquid at  $T < 40$  K. We suspect that at high temperatures the electrical transport is determined by the scattering on orbital fluctuations. For  $p < p_{\text{cr}}$  an unusu-

ally wide precursor regime was identified above the metal-insulator transition. In this regime, which is attributed to the appearance of a soft charge gap,  $\rho(t)$  can be well described by a power law of the reduced temperature. The microscopic nature of these regimes remains to be elucidated.
