Abstract
In this paper, we discuss four of the most challenging technical issues for interactions and applications in environments comprised of nowadays widespread ecologies of touch-enabled mobile and immobile devices. Such issues are important particularly for applications in the wild. We address these issues by means of an appropriate software architecture that is implemented as the reference framework Environ in order to foster interactions and applications in multi-surface environments and help bring those into the wild. The framework is available as open-source software thereby we contribute to basic enabling technologies for multi-surface environments.

Introduction
During the last decade, people’s interaction habit with daily devices has changed remarkably. While ten years ago peo-
people were used to interact with mice, touchpads and keyboards only, today, interaction with touch-enabled surfaces has become an inherent part of nowadays interaction repertoire of everyday people. More and more touch enabled mobile (smartwatches, smartphones, phablets, tablets) and immobile (tablettops, wall-mounted display) devices entered the consumer market since around 2007/2008 and the amount of device types as well as proliferation of devices is still increasing rapidly.

Hence, multi-surface environments (MSE) comprised of mobile and immobile interactive surfaces are quite likely to become commonplace in the foreseeable future. The increasing number of recent research articles targeting applications and interactions within MSEs and across multiple surfaces endorse this trend.

With the increase of MSE occurrences, the desire for cross-device interactions and applications will inevitable rise. However, issues and questions originating from differences between lab environments and outside the lab environments need to be addressed by research to enable successful transition of cross-device interactions and applications from labs into the wild.

**Outside the lab, Issues and Challenges**

Even though HCI research investigated MSEs for many years with great results, studies were conducted in controlled sterile lab environments and situations. When going into the wild, things may be different and what worked in the lab may not necessarily work in the wild. Within this paper, we briefly discuss the most challenging issues from a technical point of view and present our research aiming at those issues.

**Heterogeneity of platforms** is the most challenging issue for interaction designers as well as for application developers. While the device ecology in a lab is manageable, device ecologies in the wild are literally wild. There are different form factors (smartwatch, smartphone, phablet, tablet, etc.), different set and kind of embedded sensors (accelerometer, gyroscope, GPS, heartbeat, etc.), different operating systems (Android, iOS, Windows Phone, etc.), or different programming APIs and platform languages (Java, Objective-C, C#, etc.). Even within the same device platform, the fragmentation of the operating system may result in a multitude of differences.

**Network and device management** are interrelated and not necessarily optimal in the wild. In terms of network, there may be environments with mobile data only, with wireless network but no internet access, or multiple logically separated/connected subnets with/without internet access. In terms of device management, devices usually take part in an ad-hoc manner and may vanish suddenly which is usually the case for decentralized loosely coupled devices. Both aspects together renders centralized server-based approaches quite difficult for robustness and stability of a system in the wild.

**Performance, efficiency, stability, and low latency** have direct influence on users’ experience. Approaches that work perfectly well for one’s lab devices may require further research for other device platforms or to be scalable across device platforms.

**Security and safety** of data on devices and on transport channels are usually neglected in lab studies. However, those aspects are nowadays mandatory requirements for applications in the wild. Users would behave different or prefer different strategies in studies if they know about the safety of their data.
Development of MSE Applications

In software engineering and development practice, frameworks or toolkits are regularly used for recurrent and/or abstract tasks, e.g., node.js, jQuery, or qQt. Hence, it's conceivable that this will also be the case for development of MSE applications. For example, a multi-platform framework that automatically handles network and connectivity, or device management and communication would greatly unburden developers from implementing the required logic for each supported platform and new application which is prone to errors. Considering the high complexity induced by nowadays heterogeneous device ecologies, such an MSE framework would also be beneficial for research studies and reproduction of research results. Previous research efforts [1, 5, 7, 8] that address MSE framework concepts further confirm this assumption. However, they did not target nowadays device ecologies and the challenges in the wild. Furthermore, lack of availability of the presented frameworks and portability of the concepts (e.g., to a smartwatch) often inhibit its reuse.

We briefly describe some highlights of the multi-platform MSE framework called Environs [2] which explicitly addresses the aforementioned issues and challenges. The reference implementation together with several introduction tutorials are publicly available as open-source software in order to foster MSE research as well as development. Moreover, the framework easily enables real-time video-based interactive portals that open up a rich direction for demanding cross-device interactions and applications, e.g., aboard ships [4] or for collaborative tasks [3, 6].

Figure 4: Supported network configurations of Environs: Devices within the same network (broadcast); Devices in different networks (STUN/STUNT mechanism).

Figure 5: 3-layer architecture of Environs exemplary for the Google Android and Apple iOS platforms.

Heterogeneity of platforms is handled by Environs through a 3-layer architecture for applications, see Figure 5. The application layer represents the actual application logic and UI that may be designed and auto-generated for multiple platforms by appropriate development tools. The framework itself is implemented in the remaining two layers, whereof the API layer provides a thin object oriented API to access the native layer. Under the hood, API objects merely keep object states and function as a proxy to native calls. The native layer is realized as a common code base for all platforms and contains the majority (~90%) of the framework logic which is implemented in portable C/C++. Hence, the whole native layer can be compiled for all platforms thereby greatly reduces development time, increases manageability and maintainability, and benefits from less programming errors. Currently, Environs supports the platforms Google Android / Android Wear, Apple iOS / WatchOS / OSX, Microsoft Windows (.NET / Surface 1 / PixelSense 2 / MultiTaction Cells), and Linux.

Network and device management is completely handled by the native layer which supports devices within the same network as well as devices across different networks. Environs manages so called application environments which can further exist in logically separated areas (e.g., meeting room, office, airport), see Figure 2, thereby enable multiple separated application environments within the same physical network. Each device assigns itself into an application area with a numerical ID, see Figure 3. Devices across different networks (e.g., both devices behind firewalls) require an additional mediator service which helps connect each other by means of STUN/STUNT mechanisms known from peer-to-peer networks. Overall, devices operate in a loosely coupled decentralized network (peer-to-peer), but server-like services are still possible through specialized device nodes.

Performance, efficiency, stability, and low latency is addressed through the native C/C++ implementation and
native optimizations. Low latency network communication is based on priority handling of data types that employs low latency transport channels as well as a channel for large chunks of bulk data. For example, touch events are passed to other devices using the shortest code paths and UDP channels. Furthermore, interactive portals make use of hardware encode/decode for low latency.

Security and safety is handled transparently in the native layer by state of the art AES encryption of transport channels. Each device automatically generates its own private/public key and certificate in order to encrypt AES session keys. This is particularly important when connecting multiple locally different MSEs to one application environment over unsecured networks (internet).

Author’s Interests and Further Research
Our interest lies in research of natural and intuitive interaction techniques and enabling technologies for novel interactive portal applications in MSEs, which nowadays powerful touch-enabled device ecologies easily enable. Currently, Environs detects the location of devices within an MSE only by means of markers under mobile devices and only if they are placed on supported tabletops. Therefore, we intend to add additional position and spatial tracking of devices and users by means of location nodes within the MSE as proposed in [1] in order to investigate spatial interaction techniques for interactive portals.
